SPECIFICATION

[Title of the Invention]

PROJECTING DIRECTION CONTROL  
SYSTEM FOR VEHICLE HEADLAMP

[Claims]

[Claim 1] A projecting direction control system for a vehicle headlamp, comprising vehicle-posture detecting means for detecting variation in the posture in the direction of movement of a vehicle and light projection control means for controlling the direction of optical axis of light projected from a vehicle headlamp in response to variation in the vehicle posture, including

wheel-speed detecting means for detecting left and right wheel speeds and

posture decision means for calculating centrifugal force from the left and right wheel speeds obtained by the wheel-speed detecting means, difference between the wheel speeds, and information inherent in the vehicle including vehicle width and vehicle weight so as to apprehend a rolling condition.

[Claim 2] A projecting direction control system for a vehicle headlamp as claimed in claim 1, wherein the posture decision means calculates the strength of centrifugal force while the vehicle is making a turn by obtaining the product of the left wheel speed or right wheel speed and the difference between the left and right wheel speeds and multiplying the product by the ratio of vehicle weight to vehicle width.

[Claim 3] A projecting direction control system for a vehicle headlamp as claimed in either claim 1 or claim 2, wherein when centrifugal force acting on the vehicle is decided by the posture decision means to be great, a control range or a control response of the projecting direction involved with the vehicle headlamp is restricted.

[Claim 4] A projecting direction control system for a vehicle headlamp as claimed in one of claims 1 - 3, wherein the posture decision means performs the process of deciding a turning direction from a sign indicating the difference between the left and right wheel speeds and wherein when the vehicle is decided to be turning to the left, the optical axis of light projected from the left headlamp provided in the forepart of the vehicle is controlled, whereas when the vehicle is decided to be turning to the right, the optical axis of light projected from the right headlamp provided in the forepart of the vehicle is controlled.

[Detailed Description of the Invention]

[0001]

[Technical Field to Which the Invention Belongs]

The present invention relates to the art of preventing posture variation being misidentified as pitch variation, the posture variation being caused by rolling while a vehicle is making a turn.

[0002]

As an instrument for controlling the projecting direction of a vehicle headlamp such that the projecting direction thereof is corrected in response to variation in the vehicle posture, there is a known instrument for automatically adjusting the projecting direction of the headlamp (a so-called auto-leveling instrument) so that the projecting direction of the headlamp is held in a predetermined state even when the inclination of the vehicle changes. When applied to a headlamp system affording a large quantity of light with a discharge lamp as a light source, such an instrument is effective in improving safety as glare is prevented from being directed onto oncoming vehicles.

[0003]

The height value of a front-wheel axle portion is presumed or estimated from the information obtained by one height-detecting means (height sensor) provided in the rear-wheel axle portion of a vehicle by the use of a predetermined expression, for example, and the pitch angle of the vehicle is then obtained so as to drive the reflecting mirror of a lighting device to negate the variation of the pitch angle whereby to perform correction control in order that the angle-to-ground of an optical axis of projection light is kept at a regular angle (see Patent Document 1, for example).

[0004]

With respect to the driving condition of the vehicle, it is needed to distinguish between turning or slalom driving

and safety driving at a fixed speed that are different from each other (see Patent Documents 2, 3 and 4, for example).

[0006]

[Problems to be solved by the Invention]

In the conventional projecting direction control systems, however, it is feared that inappropriate projecting direction control may be performed in case that posture variation at the time of rolling due to the turning of a vehicle is misidentified as pitch variation.

[0007]

In the form (so-called one sensor system) of estimating the vehicle posture using the information obtained by one height detecting means (height sensor), for example, the accurate driving posture of the vehicle cannot be captured when the output of the height sensor produced by rolling during turning motion is decided to be what indicates the pitch variation, so that

the correction of an optical axis of projection light cannot be made accurately as the behavior of the system becomes unstabilized. In other words, centrifugal force has to be taken into consideration when the turning motion of the vehicle is decided and as the centrifugal force is proportional to the square of speed and inversely proportional to the slewing radius, information on the vehicle speed and the slewing radius. However, the problem is that any system of detecting the slewing radius is not simple in configuration.

[0008]

It is therefore a problem to be solved by the invention to not only calculate centrifugal force from the information obtained on lateral wheel speeds with ease but also prevent vehicle posture variation caused by rolling being misidentified as pitch variation.

[0009]

[Means for Solving the Problems]

A projecting direction control system for a vehicle headlamp according to the invention comprises vehicle-posture detecting means for detecting variation in the posture in the direction of movement of a vehicle and light projection control means for controlling the direction of optical axis of light projected from a vehicle headlamp in response to variation in the vehicle posture, including wheel-speed detecting means for detecting left and right wheel speeds and posture decision means

for calculating centrifugal force from the left and right wheel speeds obtained by the wheel-speed detecting means, difference between the wheel speeds, and information inherent in the vehicle including vehicle width and vehicle weight so as to apprehend a rolling condition.

[0010]

Accordingly, as centrifugal force can be calculated according to the information involved with the left and right wheel speeds and information inherent in the vehicle including vehicle width and vehicle weight, an amount of rolling can be apprehended accurately from the direction of centrifugal force acting on the vehicle while the vehicle is making a turn. It is thus possible to avoid misjudgment on the posture variation accompanied with rolling.

[0011]

[Mode for Carrying out the Invention]

The invention relates to a leveling instrument (so-called auto-leveling instrument) for performing projecting direction control that follows variation in the posture of a vehicle in a standing condition or a driving condition for the purpose of accurately apprehending a rolling condition while the vehicle is making a turn. More specifically, as rolling is brought about by centrifugal force during turning motion, the rolling can be converted into an amount of rolling by calculating the direction and strength of the centrifugal force and height

variation because of rolling can be prevented from being judged as pitch variation.

[0012]

Fig. 1 is a block diagram showing a basic projecting direction control system configuration for a vehicle headlamp according to the invention.

[0013]

A projecting direction control system 1 is provided with a vehicle-posture detecting means 2, a light projection control means 3 and a drive means 4. In the case of an automotive lighting device, for example, a headlamp, a fog lamp, a cornering lamp and so forth may be cited.

[0014]

The vehicle-posture detecting means 2 is used for detecting a vehicle posture (including an inclination within the vertical plane in the direction of travel) at a standstill and/or in motion. In a known arrangement to detect variation in the height of a front- or a rear-wheel axle portion using a height detecting means, the rear wheel portion of the vehicle is provided with a height sensor so as to detect variation in the vehicle height involved with the rear-wheel axle portion and simultaneously to estimate variation in the height displacement of the front-wheel axle portion.

[0015]

The information obtained by the height detecting means

2 is sent to the light projection control means 3 and a pitch angle indicating the vertically tilted posture in the direction of travel of the vehicle is calculated, so that a control amount for use in correcting an optical axis of projection light from the headlamp 5 is calculated. In this case, the light projection control means 3 uses a computing means such as a computer and the calculations for working out the vehicle pitch angle and for controlling the optical axis of projection light are processed with software.

[0016]

On receiving a signal from the light projection control means 3, the drive means 4 changes the direction of the optical axis of light projected from the headlamp 5 so as to tilt the whole lighting device or to drive optical components including a lens, a reflecting mirror, a shade and so forth. As an arrangement of performing the leveling control of the headlamp 5 by operating a mechanism for driving (or adjusting) the optical axis of projection light, using a motor and its drive circuit, for example, there is some known form of tilting a reflecting mirror on the vertical plane including the optical axis.

[0017]

A wheel-speed detecting means 6 is provided to detect the speeds of the right and left wheels (see Fig. 2). In other words, the speeds of the right and left wheels are detected separately and the information thus obtained is sent to the

light projection control means 3.

[0018]

As described later, the centrifugal force can readily be calculated from the information obtained by the wheel-speed detecting means 6 and information inherent in the vehicle such as vehicle width and vehicle weight.

[0019]

The light projection control means 3 is provided with a basic arithmetic means 3a and a posture decision means 3b (though these means are materialized with software using a computer, both means are distinguished from each other as shown in Fig. 1 for the sake of better understanding).

[0020]

The basic arithmetic means 3a is used for calculating the tilted posture of the vehicle according to the information from the vehicle-posture detecting means 2 and obtains the vehicle pitch angle according to the height information obtained and calculates the control amount for use in correcting the optical axis of projection light, for example. In other words, the basic arithmetic means 3a calculates the control amount for use in adjusting the direction of the optical axis of light projected from the headlamp 5 slightly downward when the forepart of the vehicle body is turned upward and conversely calculates the control amount for use in adjusting the direction of the optical axis of light projected from the headlamp 5 slightly

upward when the forepart of the vehicle body is turned downward (the basic arithmetic means 3a having a role of calculating the basic control amount for offsetting the change of the optical axis of projection light caused by variation in the pitch angle).

[0021]

The posture decision means 3b apprehends the rolling condition by calculating the centrifugal force during turning motion according to the information obtained by the wheel-speed detecting means 6.

[0022]

Centrifugal force  $F$  is expressed by  $F = (m \cdot V^2) / \tau (X^2)$  means the square of  $X$ ), where  $m$  = mass,  $\tau$  = slewing radius and  $V$  = vehicle speed.

[0023]

That is,  $F$  can be calculated when  $V$  and  $\tau$  are known with  $m$  as a known quantity but the problem is how to obtain  $\tau$ .

[0024]

Fig. 3 is an exemplary diagram showing a case where the vehicle makes a turn to the left and out of the arcuate arrows L and R, L represents the locus of the left wheel, whereas R represents the locus of the right wheel.

[0025]

The signs shown in Fig. 3 mean the following:

[0026]

$\omega$  = angular velocity around the center of turning O.

w = vehicle width (to be exact, the distance between the left and right wheels).

VL = left wheel speed (information obtained by left wheel speed sensor).

VR = right wheel speed (information obtained by right wheel speed sensor).

[0027]

First, VL and VR are expressed by the following equations using  $\tau$ ,  $\omega$  and w.

[0028]

$$VL = \tau \cdot \omega$$

$$VR = (\tau + w) \cdot \omega$$

Thus the following equation is formulated when difference between VR and VL is defined as  $\Delta V$ .

[0029]

$$\Delta V = VR - VL = (\tau + w) \cdot \omega - \tau \cdot \omega = w \cdot \omega$$

When  $\omega$  is sought from the equation above, the following equation is obtained.

[0030]

$$\omega = \Delta V / w = (VR - VL) / w$$

In the case of turning to the left,  $\omega$  ranges from  $VL = \tau \cdot \omega$  to  $\omega = VL / \tau$

[0031]

The centrifugal force is obtainable from  $F = m \cdot \tau \cdot (\omega^2)$  as follows:

[0032]

$$F = m \cdot \tau \cdot \omega \cdot \omega = m \cdot \tau \cdot ((VL / \tau) \cdot ((VR - VL) / w)) = (m / w) \cdot VL \cdot (VR - VL)$$

In this case, the same expression may be obtained from

$$F = m \cdot VL \cdot VL / \tau = m \cdot VL \cdot \omega = m \cdot VL \cdot (VR - VL) / w$$

[0033]

As  $m$  and  $w$  are constants inherent in the vehicle and known constants, centrifugal force  $F$  is obtainable from the following equation with  $m$  and  $w$  as a proportional constant  $K$ .

[0034]

$$F = K \cdot VL \cdot (VR - VL)$$

Thus the centrifugal force can ultimately be calculated as long as at least information on the left and right wheel speeds is available as  $VR - VL$  is made known from information on  $VL$  and  $VR$ .

[0035]

In the case of turning to the right, it is only needed to reverse the left-to-right distinction in the description above (by replacing  $VL$  with  $VR$ ).

[0036]

The posture decision means 3b calculates the centrifugal force  $F$  from the left and right wheel speeds and the difference between their speeds, and vehicle width and vehicle weight forming information inherent in the vehicle. In other words, the gained information involved with the left and right wheels is fed into

the posture decision means 3b where  $VL \cdot (VR - VL)$  or  $VR \cdot (VL - VR)$  is obtained and the result is multiplied by the ratio of vehicle weight to width m/w so as to calculate centrifugal force while the vehicle is making a turn.

[0037]

Although the amount of rolling produced during circular driving varies with the vehicle speed and slewing radius, centrifugal force is made easily obtainable only by knowing the difference between VL and VR, so that rolling can directly be converted into an amount of rolling.

[0038]

The slewing radius and centrifugal force corresponding to the left and right wheel speeds are checked in advance and the data is formed into a map or a table before being stored into memory, whereby it is possible to find centrifugal force simply from the known constants (m and w) and the left and right wheel speeds VL and VR according to the invention as compared with calculating the centrifugal force or the amount of rolling by reference to the data when turning is detected, so that processing is simplified.

[0039]

With respect to the direction of centrifugal force, the direction thereof is easily understood from the signs  $(VR - VL)$  or  $(VL - VR)$  and the strength of centrifugal force is also understood from the absolute value of  $(VL - VR)$ . Thus the

centrifugal force as well as the amount of rolling can be apprehended from both wheel speeds and the results acquired are sent from the posture decision means 3b to the basic arithmetic means 3a and reflected on the correction of the optical axis of light projected from the headlamp 5.

[0040]

The following forms may be cited, for example.

[0041]

(A) A form of restricting response to projecting direction control involved with a headlamp when centrifugal force acting on a vehicle is great.

(B) A form of restricting a projecting direction control range involved with a headlamp when centrifugal force acting on a vehicle is great.

[0042]

In the form (A), the information on the detected height is judged by the posture decision means 3b to be what includes much of the variation caused by rolling when centrifugal force acting on the vehicle exceeds a predetermined threshold and control response to the direction of the optical axis of light projected from the vehicle is slowed down (lowered). This is based on a way of thinking that when posture variation due to rolling is misjudged as pitch variation, it is feared that a mechanism for driving the optical axis of projection light quickly responds to the posture variation due to rolling in case that

basic control of the correction of the optical axis of projection light is performed without becoming aware of the misjudgment above and in order to prevent the evil effect resulting from the correction thereof, it is better not to move the optical axis of projection light frequently.

[0043]

Fig. 4 is a flowchart showing an example of control when turning is detected.

[0044]

First, data as to left wheel speed VL is acquired at Step S1 and data as to right wheel speed VR is acquired at Step S2 (this order may be reversed).

[0045]

At Step S3, an absolute value of a quantity proportional to centrifugal force  $VL \cdot (VR - VL)$ , for example, is obtained and compared with a threshold (hereinafter put down as  $\alpha$ ). In this case, the threshold  $\alpha$  is set to each car model and differs with the comparison value of m/w.

[0046]

When  $|VL \cdot (VR - VL)|$  is greater than the threshold  $\alpha$ , Step S4 is followed and when  $|VL \cdot (VR - VL)|$  is equal to or smaller than the threshold  $\alpha$ , Step S5 is followed.

[0047]

At Step S4, when the control amount for use in correcting the optical axis of projection light is calculated through the

filtering process of pitch angle data, too sensitive following toward pitch angle variation is suppressed by setting filter time (or detection time) longer. Incidentally, in such a form that the control amount obtainable by subjecting the data sampled within filter time to proper processing; for example, the control amount is obtained from the average value (moving average value) of an optical control amount within a predetermined time, based on which the direction of the optical axis of projection light is controlled, control response can be lowered by making the filter time longer (i.e., calculating the average value over a long period). Although the filter time differs with the car model, about 10 seconds may be set as a standard, for example.

[0048]

At Step S5, the correction of the optical axis of projection light is made in accordance with the result calculated by the basic arithmetic means 3a. In the form of performing a pitch-angle data filtering process, for example, the filter time may be prescribed in proportion to the vehicle speed (as the vehicle speed grows greater, the filter time is shortened).

[0049]

In the form (B), the information on the detected height is judged by the posture decision means 3b to be what includes much of the variation caused by rolling when centrifugal force acting on the vehicle exceeds a predetermined threshold and the direction of the optical axis of light projected from the

headlamp is fixed to a predetermined direction or otherwise control tolerance is reduced. This is based on a way of thinking that when posture variation due to rolling is misjudged as pitch variation, it is feared that the projecting direction is directed in an unexpected direction in case that basic control of the correction of the optical axis of projection light is performed without becoming aware of the misjudgment above and in order to prevent the evil effect resulting from the correction thereof, it is better not to greatly move the optical axis of projection light.

[0050]

Fig. 5 is a flowchart showing an example of control when turning is detected.

[0051]

According to this embodiment of the invention, Steps S1 - S3 are identical with the respective Steps S1 - S3 of Fig. 4.

[0052]

When  $|VL \cdot (VR - VL)|$  is judged to be greater than the threshold  $\alpha$  at Step S3, Step S4 is followed and the direction of the optical axis of light projected from the headlamp is fixed to a fixed direction, for example, to a direction correspond to an initial value (initial aiming value) and a control value before turning (it is desired not to move the optical axis rashly during turning motion).

[0053]

When  $|VL \cdot (VR - VL)|$  is equal to or smaller than the threshold  $\alpha$  at Step S3, Step S5 is followed and the correction of the optical axis of projection light is made in accordance with the result calculated by the basic arithmetic means 3a. Although control is performed to keep constant the angle-to-ground of the optical axis of projection light or a forward range of visibility, the result decided by the posture decision means 3b is not reflected on the correction of the optical axis of projection light.

[0054]

Fig. 6 is a flowchart showing another example of control when turning is detected and according to this embodiment of the invention, the direction of the optical axis of projection light during turning motion is fixed on the basis of the last control value involved with the correction of the optical axis of projection light or of the control value in the past for a fixed time.

[0055]

At Step S1 first, the control amount (e.g., an amount equivalent to the position or displacement of the stroking amount of an actuator) involved with the optical axis of projection light is stored into memory, which may be done at predetermined time intervals (e.g., about five seconds) or at every driving distance or every driving time interval corresponding to the

vehicle speed.

[0056]

VL is acquired at Step S2 and VR is acquired at Step S3. Then Step S4 is followed at which decision is made on turning. More specifically, the absolute value of  $VL \cdot (VR - VL)$  is obtained and compared with the threshold  $\alpha$ . When  $|VL \cdot (VR - VL)| > \alpha$ , Step S5 is followed and when  $|VL \cdot (VR - VL)| \leq \alpha$ , Step S6 is followed.

[0057]

At Step S5, the direction of the optical axis of projection light is fixed under the position control by the actuator on the basis of the control amount stored at Step S1.

[0058]

Step S6 is identical with Step S5 of Fig. 5.

[0059]

As described above, the contents of the projecting direction control involved with the headlamp are changed in proportion to the strength of centrifugal force during turning motion but with respect to the left and right headlamps provided in the forepart of the vehicle, there are a form of controlling the projecting directions simultaneously (synchronous control) and a form of controlling the projecting directions separately (asynchronous control).

[0060]

In the latter case, for example, when the posture decision

means 3b decides the turning direction from a sign indicating the difference between the left and right wheel speeds, the direction of the optical axis of light projected from only the headlamp installed on the same side as the turning direction as seen from a direction along the direction of movement of the vehicle is controlled. In other words, the direction of the optical axis of light projected from the left headlamp (left-hand side in the direction of movement) provided in the forepart of the vehicle is controlled when the vehicle is decided to be turning to the left, whereas the direction of the optical axis of light projected from the right headlamp provided in the forepart of the vehicle is controlled when the vehicle is decided to be turning to the right.

[0061]

Fig. 7 shows a flowchart showing an example of control when turning is detected as described above.

[0062]

VL is acquired at Step S1 and VR is acquired at Step S2. Then Step S3 is followed at which decision is made on turning. More specifically, the absolute value of  $VL \cdot (VR - VL)$  is obtained and compared with the threshold  $\alpha$ . When  $|VL \cdot (VR - VL)| > \alpha$ , Step S4 is followed and when  $|VL \cdot (VR - VL)| \leq \alpha$ , Step S9 is followed.

[0063]

At Step S4, the turning direction is decided from the

sign of VR - VL. In other words, Step S5 is followed when (VR - VL) > 0 and Step S6 is followed when (VR - VL) < 0.

[0064]

At Step S5, the vehicle is decided to be turning to the left from VR > VL and Step S7 is followed. At Step S5, further, the vehicle is decided to be turning to the right from VR < VL and Step S8 is followed.

[0065]

In consideration of the fact that one side of the vehicle body to which the vehicle makes a turn tends to float up during turning motion, the optical axis of light projected from one headlamp, out of the left and right headlamps, corresponding to the turning direction is corrected (in the following description, the left and right sides are defined as the vehicle is seen along the direction of movement of the vehicle, that is, seen from the rear of the vehicle to the front thereof).

[0066]

In the case of turning to the left, for example, the direction of the optical axis of light projected from only the left headlamp is controlled at Step S7. In other words, with variation in the posture of the left portion of the vehicle, the optical axis of light projected from the headlamp is controlled so that it is not excessively tilted upward. In the case of turning to the right, further, the direction of the optical axis of light projected from only the right headlamp is controlled

at Step S8. In other words, with variation in the posture of the right portion of the vehicle, the optical axis of light projected from the headlamp is controlled so that it is not excessively tilted upward.

[0067]

Step S9 is identical with Step S5 of Fig. 5.

[0068]

With the arrangement above, moreover, the following advantages are available.

[0069]

.Information on the left and right wheel speeds changing from moment to moment is acquired, whereby centrifugal force can be calculated from these pieces of information and information inherent in the vehicle (including vehicle width and weight), and the direction of the optical axis of projection light can be performed properly in response to the rolling condition (variation in the posture due to rolling can be apprehended accurately on the basis of centrifugal force).

[0070]

.From the difference ( $VR - VL$ ) or ( $VL - VR$ ) between the left and right wheel speeds, the turning direction is made known by distinguishing between positive and negative. When the fitting position of the height sensor is leftish or rightish with respect to the vehicle body, the information obtained by the sensor varies with the fitting position even though the

slewing radius remains unchanged during turning motion to the left or right. Consequently, an offset component (corresponding to the deviated amount of the fitting position with the center axis of the vehicle extended in the direction of movement of the vehicle and coming to zero when a fitting error is disregarded with the fitting position situated on the center axis of the vehicle body) is produced. On condition that the leftish and rightish turnings are distinguishable from each other, the effect of the offset component can be removed (in case that the turning direction is unknown, it is feared that the posture variation based on the asymmetry of the fitting position of the sensor can be overestimated or underestimated depending on the turning direction).

[0071]

When the sensor output caused by rolling during turning motion is decided to be dependent on the pitch variation in the form of providing only the front- or rear-wheel axle portion with the height sensor, there develops a problem of making the output of any other height sensor incomparable. However, the vehicle posture can be apprehended more accurately since a rolling generating condition is calculated quantitatively by seeking centrifugal force from the left and right wheel speeds as described above.

[0072]

Accuracy in the detection of the turning condition can

needless to say be increased by applying the invention to not only the one sensor system but also the form of attaching height detecting means to the respective front- and rear-wheel axle portions (so-called two sensor system).

[0073]

[Effect of the Invention]

As is obvious from the description given above, according to the invention as described in claim 1, the correction of the optical axis of projection light can be made accurately by calculating the information involved with the left and right wheel speeds and information inherent in the vehicle including the width and weight of the vehicle so as to apprehend the rolling condition.

[0074]

According to the invention as described in claim 2, centrifugal force can simply be calculated from the left and right wheel speeds, the difference between the wheel speeds and vehicle weight and width, so that it is not needed to directly find the slewing radius when the centrifugal force is calculated.

[0075]

According to the invention as described in claim 3, when the amount of rolling produced by the centrifugal force during turning motion is great, the control range or the control response of the projecting direction is restricted, whereby the optical axis of projection light is prevented from being corrected

improperly.

[0076]

According to the invention as described in claim 4, proper control is performable by correcting the direction of the optical axis of light projected from the headlamp on only one side is made in response to the turning direction so as to distinguish between different behaviors involved with the turning direction.

[Designation of Document]

## ABSTRACT

[Abstract]

[Problem] To not only calculate centrifugal force from the information obtained on lateral wheel speeds with ease but also prevent vehicle posture variation caused by rolling being misidentified as pitch variation.

[Means for Solving the Problem] A projecting direction control system 1 for a vehicle headlamp 5 is provided with wheel-speed detecting means 6 for detecting left and right wheel speeds and posture decision means 3b for calculating centrifugal force from the left and right wheel speeds obtained by the wheel-speed detecting means, difference between the wheel speeds, and information inherent in the vehicle including vehicle width and vehicle weight so as to apprehend a rolling condition. The rolling condition can be apprehended accurately from the direction and strength of the centrifugal force by calculating the centrifugal force during turning motion.
